# 1 Introduction

The size of components in classical computers is shrinking exponentially, if trends continue soon the behavior of the components will be dominated more by quantum physics than classical physics. Researchers have begun investigating the implications of these quantum behaviors on computation. Surprisingly, it seems that a computer whose components are able to function in a quantum manner may be more powerful than any classical computer can be.

The study of quantum physics has shown that the behaviors of physical systems understood from classical physics break down in systems of sufficiently small scale. The scale which these classical assumptions break down is the scale we are rapidly approaching with components in modern computers. At the current rate of miniaturization memory components will reach the size of about one atom per bit around the year 2020. At this size the storage for a bit cannot be expected to behave in a classical manner, and the size of an elementary particle is an absolute lower bound for the classical bit size. This bound does not hail the eventual end to advances in computing hardware. The same quantum effects which will prevent the continual miniaturization of classical computers may allow the development of a quantum computer, which relies upon these quantum effects.

At the heart of quantum computing lies parallelism. This inherent parallelism, make simulation of a quantum system an ideal candidate for speedup through conventional parallelism.

## 2 The Quantum Computer

### 2.1 The Classical Bit

In a classical computer a bit is typically stored in a silicone chip, a metal hard drive platter, or on a magnetic tape. About  $10^5$  atoms are currently used to represent one bit of information. The smallest conceivable storage for a bit involves a single elementary particle of some sort. For example a spin-1/2 of particle, which can be characterized by its spin value. The spin is measured to be either  $+1/2$  or  $-1/2$ . We can encode 1 to be  $+1/2$  and 0 to be  $-1/2$ , and if we assume we can measure and manipulate the spin of such a particle then we could theoretically use this particle to store one bit of information. If we were to try to use this spin-1/2 particle as a classical bit, one that is always in the 0 or 1 state, we would fail. This single spin-1/2 particle will instead act in a quantum manner. (Williams, Clearwater)

### 2.2 The Quantum Bit

This spin-1/2 particle which behaves in a quantum manner could be the fundamental building block of a Quantum computer. We could call it a qubit, to denote that it is analogous in some ways to a bit in a classical computer. Just as a memory register in a classical computer is an array of bits, a quantum

memory register is composed of several spin-1/2 particles, or qubits. There are a multitude of possible qubit representations that will work. For simplicity only the spin-1/2 particle will be discussed from here on.

### 2.3 State Vectors and Dirac Notation

We wish to know exactly how the behavior of the spin-1/2 particle, our qubit, differs from a that of a classical bit. A classical bit can store either a 1 or a 0, and when measured the value observed will always be the value stored. Quantum physics states that when we measure the spin-1/2 particles state we will determine that it is in the +1/2 state, or the spin -1/2 state. In this manner our qubit is not different from a classical bit, for it can be measured to be in the +1/2, or 1 state, or the -1/2, or 0 state. The differences between the qubit and the bit come from what sort of information a qubit can store when it is not being measured.

According to quantum physics we may describe that state of this spin-1/2 particle by a state vector in a Hilbert Space. A Hilbert Space is a complex linear vector space.

A complex vector space is one in which the lengths of the vectors within the space are described with complex numbers. A linear vector space is one that you may add and multiply vectors that lie in the space and the resulting vector will still lie within that space. (Williams, Clearwater)

The Hilbert Space for a single qubit will have two perpendicular axes, one corresponding to the spin-1/2 particle being in the +1/2 state, and the other to the particle being in the -1/2 state. These states which the vector can be measured to be are referred to as "eigenstates." The vector which exists somewhere in this space which represents the state of the spin-1/2 particle is called the "state vector." The projection of the state vector onto one of the axes shows the contribution of that axes' eigenstate to the whole state. This means that in general, the state of the spin-1/2 particle can be any combination of the base states. In this manner a qubit is totally unlike a bit, a bit can exist in only the 0 or 1 state, but the qubit can exist, in principle, in any combination of the 0 and 1 states, and is only constrained to be in the 0 or 1 state when measured.

We introduce here the standard notation for state vectors in Quantum physics. The state vector is written the following way is called a "ket vector"  $|\psi\rangle$ . Where  $\psi$  is a list of numbers which contain information about the projection of the state vector onto its base states. The term ket and this notation come from the physicist Paul Dirac who wanted a concise shorthand way of writing formulas that occur in Quantum physics. These formulas frequently took the form of the product of a row vector with a column vector. Thus he referred to row vectors as "bra vectors" represented as  $\langle y|$ . The product of a "bra" and a "ket" vector would be written  $\langle y|x\rangle$ , and would be referred to as a "bracket." (Williams, Clearwater)

## 2.4 Superposition and Eigenstates

Earlier we said that the projection of the state vector onto one of the perpendicular axes of its Hilbert Space shows the contribution of that axes' eigenstate to the whole state. According to quantum physics a quantum system can exist in a mix of all of its allowed states simultaneously. While the physics of superposition is not simple at all, mathematically it is not difficult to characterize this kind of behavior.

## 2.5 The Quantum qubit

Back to our qubit, the spin-1/2 particle. We know that while it can only be measured to have a spin of +1/2 or -1/2, it may in general be evolve into a superposition of these states between measurements.

Let  $x_1$  be the eigenstate corresponding to the spin +1/2 state, and let  $x_0$  be the eigenstate corresponding to the spin -1/2 state. Let  $X$  be the total state of the state vector, and let  $w_1$  and  $w_0$  be the complex numbers that weight the contribution of the base states to the total state, then in general:

$$|X \rangle = w_0 * |x_0 \rangle + w_1 * |x_1 \rangle == (w_0, w_1)$$

At this point it should be remembered that  $w_0$  and  $w_1$ , the weighting factors of the base states are complex numbers, and that when the state of  $X$  is measured, we are guaranteed to find it to be in either the state:

$$0 * |x_0 \rangle + w_1 * |x_1 \rangle == (0, w_1)$$

or the state

$$w_0 * |x_0 \rangle + 0 * |x_1 \rangle == (w_0, 0)$$

The state vector is a unit vector in a Hilbert space, which is similar to vector spaces you may be more familiar with, but it differs in that the lengths of the vectors are complex numbers. It is not necessary from a physics perspective for the state vector to be a unit vector (meaning it has a length of 1), but it makes for easier calculations further on, so we will assume from here on out that the state vector has length 1. This assumption does not invalidate any claims about the behavior of the state vector.

Thus we have fully defined the basic building block of a quantum computer, the qubit. It is fundamentally different from a classical bit in that it can exist in any superposition of the 0 and 1 states when it is not being measured. (Barenco, Ekert, Sanpera, Machiavello)

## 2.6 The Quantum Memory Register

We have thus far considered a two state quantum system, specifically a spin-1/2 particle. However a quantum system is by no means constrained to be a two state system. Much of the above discussion for a two state quantum system is applicable to a general  $n$  state quantum system.

In an  $n$  state system the Hilbert Space has  $n$  perpendicular axes, or eigenstates, which represent the possible states that the system can be measured in. As with the two state system, when we measure the  $n$  state quantum system, we will always find it to be in exactly one of the  $n$  states, and not a superposition of the  $n$  states. The system is still allowed to exist in any superposition of the  $n$  states between measurements.

Just as a two state quantum system with coordinate axes  $x_0, x_1$  can be fully described by:

$$|X \rangle = w_0 * |x_0 \rangle + w_1 * |x_1 \rangle = (w_0, w_1)$$

An  $n$  state quantum system with coordinate axes  $x_0, x_1, \dots, x_{n-1}$  can be fully described by:

$$|X \rangle = \sum_{k=0}^{n-1} w_k * |x_k \rangle$$

In general a quantum system with  $n$  base states can be represented by the  $n$  complex numbers  $w_0$  to  $w_{n-1}$ . When this is done the state may be written:

$$|X \rangle = \begin{pmatrix} w_0 \\ w_1 \\ \vdots \\ w_{n-1} \end{pmatrix}$$

Where it is understood that  $w_k$  refers to the complex weighting factor for the  $k$ 'th eigenstate.

Using this information we can construct a quantum memory register from the qubits described in the previous section. Note that in general a quantum register composed of  $n$  qubits requires  $2^n$  complex numbers to completely describe its state. A  $n$  qubit register can be measured to be in one of  $2^n$  states, and each state requires one complex number to represent the projection of that total state onto that state. In contrast a classical register composed of  $n$  bits requires only  $n$  integers to fully describe its state.

This means, in some sense, that one can store an exponential amount of information in a quantum register. Here we see some of the first hints that a quantum computer can be exponentially more powerful than a classical computer in some respects.

## 2.7 Probability Interpretation

Now that we know how to represent a state vector as a superposition of states, and yet can only measure the state vector to be in one of the base states. We must determine what happens when we measure the state vector.

The only way to observe the state of the state vector is to in some way cause the quantum mechanical system to interact with the environment. When the state vector is observed it makes a sudden discontinuous jump to one of the eigenstates. (Williams, Clearwater)

To perform any sort of useful calculation we must be able to say something about which base state into which a quantum mechanical system will collapse. The probability that the state vector will collapse into the  $j$ 'th eigenstate is given by  $|w_j|^2$ , which is defined to be  $a_j^2 + b_j^2$  if  $w_j = a_j + i * b_j$ , where  $w_j$  is the complex projection of the state vector onto the  $j$ 'th eigenstate. In general the chance of choosing any given state is

$$Prob(j) = \frac{|w_j|^2}{\sum_{k=0}^{n-1} |w_k|^2}$$

but as mentioned earlier we will insist on having the state vector of length one, and in this case the probability expression simplifies to  $Prob(j) = |w_j|^2$ .

## 2.8 Quantum Parallelism

Quantum parallelism arises from the ability of a quantum memory register to exist in a superposition of base states. Each component of this superposition may be thought of as a single argument to a function. A function performed once on the register in a superposition of states is performed on each of the components of the superposition. Since the number of possible states is  $2^n$  where  $n$  is the number of qubits in the quantum register, you can perform in one operation on a quantum computer what would take an exponential number of operations on a classical computer. This is fantastic, but the more superposed states that exist in your register, the smaller the probability that you will measure any particular one becomes.

Suppose that you are using a quantum computer to calculate the function  $\mathcal{F}(x) = 2 * x \bmod 7$ , where  $x$  is the superposition of integers between 0 and 7 inclusive. You could prepare a quantum register that was in an equally weighted superposition of the states 0-7. Then you could perform the  $2 * x \bmod 7$  operation once, and the register would contain the equally weighted superposition of 1,2,4,6,1,3,5,0 states, these being the outputs of the function  $2 * x \bmod 7$  for inputs 0 - 7. When measuring the quantum register you would have a 2/8 chance of measuring 1, and a 1/8 chance of measuring any of the other outputs. It would seem that this sort of parallelism is not useful, as the more we benefit from parallelism the less likely we are to measure the value of the calculated function for a particular input. Some clever algorithms have been devised, most notably Peter Shor's factoring algorithm, which succeed in using quantum parallelism on a function where there is interest in some property of all the inputs, not just a particular one.

This kind of parallelism is very appealing for simulation on a parallel computer. A  $n$  bit quantum register contains a superposition of each of its  $2^n$  possible base states, and we represent this by an array of  $2^n$  complex numbers which are probabilities of measuring the quantum register to be the corresponding base state. To perform an operation on the quantum register, we simply modify each of the  $2^n$  array locations. The calculations are independent of one another. By splitting the calculation of how to change the probability value

of the array locations into even ranges, and assigning each range to a process elements, we can expect to achieve nearly linear speedup.

## 3 Shor's Algorithm

### 3.1 Introduction to Shor's Algorithm

By 1993 it was known that a quantum computer could perform certain tasks asymptotically faster than a Turing Machine. Nonetheless research into quantum computing was largely driven by academic curiosity. In 1994 Peter Shor, a scientist working for Bell Labs, devised a polynomial time algorithm for finding prime factors of large numbers on a quantum computer. This discovery drew great attention to the field of quantum computing.

Shor's algorithm is viewed as important because the difficulty of finding prime factors of large numbers is relied upon for most cryptography systems. If an efficient method of factoring large numbers were to be discovered, most of the current encryption schemes would be easily compromised. While it has not been proven that factoring large numbers can not be archived on a classical computer in polynomial time, the fastest published algorithm for factoring large number runs in  $O(e^{c(\log n)^{1/3} * (\log \log n)^{2/3}})$ , or exponential time. In contrast Shor's algorithm runs in  $O((\log n)^2 * \log \log n)$  on a quantum computer, and then must perform  $O(\log n)$  steps of post processing on a classical computer. Overall this time is polynomial. This discovery propelled the study of quantum computing forward, as such an algorithm is much sought after. (Shor)

### 3.2 Overview of Shor's Algorithm

Shor's algorithm hinges on a result from number theory. This result is: The function  $\mathcal{F}(a) = x^a \bmod n$  is a periodic function, where  $x$  is an integer coprime to  $n$ . In the context of Shor's algorithm  $n$  will be the number we wish to factor. When two numbers are coprime it means that their greatest common divisor is 1.

Calculating this function for an exponential number of  $a$ 's would take exponential time on a classical computer. Shor's algorithm utilizes quantum parallelism to perform the exponential number of operations in one step.

Since  $\mathcal{F}(a)$  is a periodic function, it has some period  $r$ . We know that  $x^0 \bmod n = 1$ , so  $x^r \bmod n = 1$ , and  $x^{2r} \bmod n = 1$  and so on since the function is periodic.

Given this information and through the following algebraic manipulation:

$$\begin{aligned}x^r &\equiv 1 \pmod{n} \\(x^{r/2})^2 &= x^r \equiv 1 \pmod{n} \\(x^{r/2})^2 - 1 &\equiv 0 \pmod{n}\end{aligned}$$

and if  $r$  is an even number

$$(x^{r/2} - 1)(x^{r/2} + 1) \equiv 0 \pmod{n}$$

We can see that the product  $(x^{r/2} - 1)(x^{r/2} + 1)$  is an integer multiple of  $n$ , the number to be factored. So long as  $x^{r/2}$  is not equal to  $\pm 1$ , then at least one of  $(x^{r/2} - 1)$ ,  $(x^{r/2} + 1)$  must have a nontrivial factor in common with  $n$ . So by computing  $\gcd(x^{r/2} - 1, n)$ , and  $\gcd(x^{r/2} + 1, n)$ , we will obtain a factor of  $n$ , where  $\gcd$  is the greatest common denominator function.

### 3.3 Steps to Shor's Algorithm

Shor's algorithm for factoring a given integer  $n$  can be broken into some simple steps.

1. Determine if the number  $n$  is a prime, a even number, or an integer power of a prime number. If it is we will not use Shor's algorithm. There are efficient classical methods for determining if a integer  $n$  belongs to one of the above groups, and providing factors for it if it is. This step would be performed on a classical computer.
2. Pick a integer  $q$  that is the power of 2 such that  $n^2 \leq q < 2n^2$ . This step would be done on a classical computer.
3. Pick a random integer  $x$  that is coprime to  $n$ . There are efficient classical methods for picking such an  $x$ . This step would be done on a classical computer.
4. Create a quantum register and partition it into two regions, register 1 and register 2. Thus the state of the quantum computer is given by:  $|\text{reg1}, \text{reg2}\rangle$ . Register 1 must have enough qubits to represent integers as large as  $q - 1$ . Register 2 must have enough qubits to represent integers as large as  $n - 1$ . The calculations for how many qubits are needed would be done on a classical computer.
5. Load register 1 with an equally weighted superposition of all integers from 0 to  $q - 1$ . Load register 2 with all zeros. This operation would be performed by the quantum computer. The total state of the quantum memory register at this point is:

$$\frac{1}{\sqrt{q}} \sum_{a=0}^{q-1} |a, 0\rangle$$

6. Now apply the transformation  $x^a \pmod{n}$  to for each number stored in register 1 and store the result in register 2. Through quantum parallelism this will take only one step, as the quantum computer will only calculate  $x^{|a\rangle} \pmod{n}$ , where  $|a\rangle$  is the superposition of states created in step

5. This step is performed on the quantum computer. The state of the quantum memory register at this point is:

$$\frac{1}{\sqrt{q}} \sum_{a=0}^{q-1} |a, x^a \bmod n \rangle$$

7. Measure the second register, and observe some value  $k$ . This has the side effect of collapsing register 1 into a equal superposition of each value  $a$  between 0 and  $q - 1$  such that

$$x^a \bmod n = k$$

This operation is performed by the quantum computer. The state of the quantum memory register after this step is:

$$\frac{1}{\sqrt{|A|}} \sum_{a'=a' \in A} |a', k \rangle$$

Where  $A$  is the set of  $a$ 's such that  $x^a \bmod n = k$ , and  $|A|$  is the number of elements in that set.

8. Now compute the discrete Fourier transform on register one. The discrete Fourier transform when applied to a state  $|a \rangle$  changes it in the following manner:

$$|a \rangle = \frac{1}{\sqrt{q}} \sum_{c=0}^{q-1} |c \rangle * e^{2\pi i a c / q}$$

This step is performed by the quantum computer in one step through quantum parallelism. After the discrete Fourier transform our register is in the state:

$$\frac{1}{\sqrt{|A|}} \sum_{a' \in A} \frac{1}{\sqrt{q}} \sum_{c=0}^{q-1} |c, k \rangle * e^{2\pi i a' c / q}$$

9. Measure the state of register one, call this value  $m$ , this integer  $m$  has a very high probability of being a multiple of  $q/r$ , where  $r$  is the desired period. This step is performed by the quantum computer.
10. Take the value  $m$ , and on a classical computer do some post processing which calculates  $r$  based on knowledge of  $m$  and  $q$ . This post processing is done on a classical computer.
11. Once you have attained  $r$ , a factor of  $n$  can be determined by taking  $\gcd(x^{r/2} + 1, n)$  and  $\gcd(x^{r/2} - 1, n)$ . If you have found a factor of  $n$ , then stop, if not go to step 4. This final step is done on a classical computer.

Step 11 contains a provision for what to do if Shor's algorithm failed to produce factors of  $n$ . There are a few reasons why Shor's algorithm can fail; the discrete Fourier transform could be measured to be 0 in step 9, the algorithm will sometimes find factors of 1 and  $n$ . For these reasons step 11 must be able to jump back to step four to start over. (Williams, Clearwater)

### 3.4 Parallelizing Shor's Algorithm

The vast majority of the time spent in the processing of Shor's algorithm is in the discrete Fourier transform step. In the discrete Fourier transform we iterate from 0 to  $q$ , and for each possible value in that range we iterate over the entire register and perform some mathematical operations. It is possible to evenly divide work in this process amongst the process elements.

In general Shor's algorithm simulation seems a good candidate for parallelization. The simulation can roughly be divided into three phases pre-processing, simulation of the quantum register, and post processing. During the simulation of the quantum register, all the work is done in the form of applying the same operation to an entire array, where each array location represents one of the base states of the quantum register.

## 4 A Simulation of Shor's Algorithm on a Classical Computer

The simulation implements all of the steps in Shor's algorithm, and successfully factors numbers. All of the simulation code is written in C++ and can be found in appendix D.

### 4.1 Introduction to the Code for the Simulation

The code base for the simulation of Shor's algorithm consists of eight files.

`complex.h/C`: These files contain the simple complex number class that we wrote for storing state information about the quantum memory register in the simulation.

`qreg.C`: This file contains the quantum register class that simulates the behavior of the quantum memory register in Shor's algorithm. It is generic enough that it may be made to simulate any quantum memory register, although what happens in the event of a collapse not due to the direct measurement of the register is left to the programmer to perform. An example of such a collapse that is the collapse of the first partition of Shor's quantum memory register in step 7 of his algorithm.

`util.C`: This is a library of functions used by `shor.C`

`timer.C`: Function for measuring the running time of Shor's algorithm.

`barrier.h`: Contains code supporting barriers, where threads must synchronize.

`range.h`: Contains code for splitting up work between threads.

`shor.C`: Contains the simulation of the steps of Shor's algorithm.

### 4.2 The Simulation of Shor's Algorithm

The implementation of Shor's algorithm found in `shor.C` follows the steps outlined in the description of Shor's algorithm found above. There are some signif-

icant differences in the behavior of the simulator and the behavior of a actual quantum computer.

The simulator uses  $2^{n+1}$  double precision floating point numbers to represent the state of the quantum register. It uses one Complex object to represent the probability amplitude of each of the  $2^n$  eigenstates of a  $n$  bit quantum memory register, and each Complex object uses two double precision floating point numbers. A real quantum computer would use exactly  $n$  qubits as its memory register. This exponential space usage is unavoidable, as a classical computer cannot simulate a quantum computer without suffering from exponential time and space usage.

A second large difference is that during the modular exponentiation step of Shor's algorithm (Step 6 above) a quantum computer would perform one operation of  $x^a \bmod n$ , where  $a$  is the superposition of states in register 1. The simulation must calculate the superposition of values caused by calculating  $x^a \bmod n$  for  $a = 0$  through  $q - 1$  iteratively. The simulation also stores the result of each modular exponentiation, and uses that information to collapse register 1 in step 7 in Shor's algorithm. A quantum computer would not be capable of performing this book keeping, as examining any particular result would collapse the existing superposition to be placed in register 2 at the end of step 6 of Shor's algorithm. A quantum computer would have no need whatsoever to do such book keeping, as when register 2 is measured in step 7, the collapse of register 1 is an automatic and unavoidable consequence of the measurement. A analogous argument follows for the use of the get probability function in step 8 of Shor's algorithm for calculating the discrete Fourier transform.

Aside from these differences, which are necessitated by the inability of a classical computer to accurately depict the behavior of a quantum mechanical system, the operations are performed by the shor.C program are identical to those called for in the description of Shor's algorithm.

As the algorithm runs the state of the quantum memory register changes in the manner laid out in the description of Shor's algorithm. After the final measurement of register 1 in step 9 we obtain some integer  $m$ , which has a high probability of being an integer multiple  $\lambda$  of  $q/r$ .  $r$  is the period of  $x^a \bmod n$  that we are trying to find, so that we may calculate  $x^{r/2} - 1 \bmod n$  and  $x^{r/2} + 1 \bmod n$  in an effort to find numbers which share factors with  $n$ .

In the post processing step shor.C takes the integer  $m$  and divides it by  $q$ , thus yielding some number  $c$  which is approximately equal to  $\lambda/r$ , where  $\lambda$  is an integer, and  $r$  is the desired period. Then using a helper function it calculates the best rational approximation to  $c$  which has a denominator that is less than or equal to  $q$  (recall that  $q$  is the power of two such that  $n^2 \leq q < 2n^2$ , where  $n$  is the number to be factored by Shor's algorithm). The period must be less than or equal to  $q$ , because there are only  $q$  values total.

We take this denominator to be the desired period. Shor's algorithm can only use even periods in determining factors of  $n$ , and so we check to see if  $r$  is even, if not we check to see if doubling the period would still yield a period less than  $q$ , if so we double the guessed period.

Taking the period, which is now guaranteed to be even, we proceed to calcu-

late  $x^{r/2} - 1 \pmod n$  and  $x^{r/2} + 1 \pmod n$ , calling these values  $a$  and  $b$ , we compute the greatest common denominator of  $a$  and  $n$ , and  $b$  and  $n$ , to see if we have attained a nontrivial factor of  $n$ .

### 4.3 Parallelizing Methodology

There is a strong correlation between the portions of Shor's algorithm which would be performed on a classical computer, portions which would be performed on a quantum computer, and portions of the simulation that do not parallelize, and portions that do.

The parts of Shor's algorithm which are pre and post processing which take place on a classical computer are not good candidates for parallelization. In contrast, the portions which the quantum computer would perform are easily parallelized.

The basis for parallelization in the simulation of Shor's algorithm is that at several points in the sequential code there are loops which iterate over large arrays, and modify each element in some uniform manner.

Given this type of parallelism, each of the Charm++, pthreads, and MPI paradigms has some appeals and disadvantages. Charm++'s object paradigm coincides with the sequential code's object oriented approach. Charm++'s load balancing features are not of much utility, as the workload between even array portions is very even to start with, and it is not clear that the overhead imposed by Charm++ would be recovered by superior load balancing. MPI seems reasonable, as each process element iterates over its own exclusive region in the parallelized code, however, we then must communicate each portion to a manager processor, who would perform various operations.

Pthreads seemed the most natural version, since each thread iterates over its unique set of array locations, there is no need for locks, and no danger of deadlock or data corruption. If the array locations are suitably large, there is very little false sharing due to different array portions existing in the same cache lines of different threads. Once deciding on the pthreads paradigm, there are two hurdles that must be overcome. We must decide on a synchronization method, and we must decide how to split work.

Splitting the work is achieved in `range.h`, where given the values of  $n$ ,  $q$ , and `num pthreads`, we assign values to each of `num pthreads` array locations, such that the  $i$ 'th array location of `q range lower`, `q range upper`, `n range lower` and `n range upper` contains the array locations where the  $i$ 'th process element should begin and end processing.

Setting barriers is achieved in `barrier.h`. We simply implement a barrier with pthread locks. These barriers occur before and after each of the parallel sections. They are necessary because frequently we perform an operation that involves some result of the entire array just before or after these parallelized sections.

In accordance with Amdahl's law our speedup is limited by the speedup of the parallelized sections, but the parallelized sections are such a large portion of the total running time, that the speedup is nearly linear.

## 5 Timing Results and speedup

Even given the small amount of code that was parallelized, we achieved remarkably good speedup results.

As can be seen, there is not a strong correlation between number of processors and run time for the trials factoring 15 (4 bits), although this can be accounted for by the fact that the run time is so small initially, and for all number of threads the run time is less than one fifth of a second. This will change rapidly, as the running time grows exponentially with the number of bits in  $n$ , the number to be factored.

In this graph for the factoring of 21 (5 bits), we begin to see possible speedup due to multiple threads, although it is still sporadic, again, this is not surprising due to the very small running times of the sequential version.

In this graph for running times and speedups while factoring 33 (6 bits), we see the beginning of our linear speedup with the number of pthreads. With the exception of the speedup for two threads, we follow a roughly linear speedup curve.

In the graph for the speedup with thread increase while factoring 77 (7 bits) we see even better behavior than we did for factoring 33. There is initially linear speedup, but once the run time gets sufficiently small, the speedup drops off, here we can see the results of the sequential time becoming the dominant portion of the running time.

In the graph for speedup and decrease run time while factoring 221 (8 bits) we see super linear speedup, which is as good as we can possibly hope for.

In the graph of speedup while factoring 391 (9 bits), we see that the good behavior while factoring 221 continues. At this point the exponential slowdown made it difficult to continue gathering speedup data for larger numbers.

## 6 Conclusion

These quantum memory registers may facilitate exponential computational speed increases by taking advantage of quantum parallelism.

Peter Shor has developed an algorithm which makes factoring large numbers tractable, and in doing so has drawn great attention to the field of quantum computing. Due to Shor's algorithm, we may someday have to turn to other means of encrypting data than currently employed.

## 8 Glossary

This is a glossary of terms and variables used throughout this paper.

$\lambda$ : In the context of Shor's algorithm in integer such that  $m = \frac{\lambda a}{r}$ .

$a$ : An argument to the function  $\mathcal{F}(a) = x^a \bmod n$ . It may be a single integer, or it may denote a superposition of states.

Binary: The base two number system. For more information see Appendix A.

Bit: A thing which can store one item of information, either a 1 or a 0.

Church-Turing Thesis, the hypothesis that:

Every 'function which would naturally be regarded as computable' can be computed by the universal Turing machine.

Classical computer: A computer whose internal workings behave in manner consistent with classical physics. Data registers in a classical computer can not exist in a superposition of states.

Classical physics: The model that was used to describe physical phenomenon before the advent of quantum physics. The predictions of classical physics with regard to the behavior of fundamental particles are incorrect.

Collapse: How the state vector of a quantum mechanical system changes when that system is observed or measured. Since the system can only be measured to be in one of its base states, the state vector will collapse from some superposition of base states into the measured state only.

Complex number: A number of the form  $a + i * b$ , where  $a$  and  $b$  are real numbers and  $i$  is defined to be the square root of negative one.

Complex vector space: A vector space in which the coordinates of a vector are complex numbers.

Coprime: Integers  $a$  and  $b$  are coprime if their greatest common denominator is one.

Discrete Fourier Transform: In Shor's algorithm this numerical method is used to calculate the multiple of the inverse period, which enables Shor's algorithm to find factors of a number  $n$ .

Exponential: A function which grows as:  $\mathcal{F}(x) = a^x$ , where  $a$  is some constant.

Exponential time: This is an attribute of an algorithm which means the number of operations required to compute the answer grows exponentially with the size of the input.

gcd: This is an abbreviation for the mathematical function which calculates the greatest common denominator of two integers. The greatest common denominator of two integers  $a$  and  $b$  is the largest integer  $c$  such that  $a/c$  and  $b/c$  are integers.

Hilbert Space: A complex linear vector space. The complete state of a  $n$  state quantum mechanical system can be represented by a vector in an  $n$  dimensional Hilbert Space.

$i$ : The square root of  $-1$ .

Linear vector space: A vector space in which a vector which is added to or multiplied by another vector results in a vector which lies within the vector space.

Memory register: A array of memory bits, a register of size  $n$  may store one of  $2^n$  values.

Mutually perpendicular: In the context of vector spaces mutually perpendicular vectors are vectors such that no one can be decomposed into components of the others.

$n$ : In the context of Shor's algorithm, a number to be factored.

Periodic function: A function with a period  $r$  such that  $\mathcal{F}(x) = \mathcal{F}(x + r) = \mathcal{F}(x + 2r)$  and so on. Sine and Cosine are periodic functions.

Polynomial time: This is an attribute of an algorithm meaning that the number of operations required to compute the answer grows polynomially with the size of the input.

$q$ : In the context of Shor's algorithm the power of 2 such that  $n^2 \leq q < 2n^2$ .

Quantum memory register: A array of  $n$  qubits which can exist in any superposition of its  $2^n$  base states.

Quantum parallelism: The ability of a quantum computer to perform an operation on a quantum memory register which results in the simultaneous calculation of a function on all superposed values in the quantum memory register.

Quantum physics: Currently the most complete model for describing the behavior of physical systems.

Qubit: A two state quantum mechanical system, which can exist in any superposition of the 0 and 1 state. In this paper I have considered a spin-1/2 particle as a possible candidate for a qubit's physical implementation.

$r$ : In the context of Shor's algorithm the period of the periodic function  $x^a \bmod n$ .

Shor's Algorithm: An algorithm designed by Peter Shor of Bell Labs which finds factors of a number  $n$  in polynomial time on a quantum computer.

Spin-1/2 particle: A fundamental particle, by which I mean it has no components, which can be characterized as having a spin of  $+1/2$  or  $-1/2$ .

State vector: The vector in a Hilbert Space which completely describes a quantum mechanical state vector.

Superposition: A mixture of base states. The state vector for a quantum mechanical systems, which can be measured in one of  $n$  base states, can in general exist in any combination of components of the base states.

Turing machine: A theoretical computing device consisting of an infinite tape divided into cells which can hold a 1, a 0, or a blank and a head which can move around the tape, read and write bits, and change its own internal state. The Church-Turing Thesis hypothesizes that any computation which can be done on a classical computer can be done on a Turing machine.

Unit vector: A vector whose length is 1.

$x$ : In the context of Shor's algorithm a integer which is coprime to  $n$  and used in the function  $\mathcal{F}(a) = x^a \bmod n$ .

## A Mathematics Used in this Paper

This appendix will review some of the mathematics used in the paper that you may not be familiar with. The sections are not intended to be comprehensive for their topic, they only cover what is needed to understand this paper.

### A.1 Binary Representation of Numbers

We commonly represent number in base 10, there are 10 elements in our base 10 numbering system, 0, 1, 2, 3, 4, 5, 6, 7, 8, and 9. In a base  $n$  counting system there are  $n$  distinct elements, 0 through  $n - 1$ .

When a number which is greater than  $n - 1$  needs to be displayed in base  $n$  it is represented by a string composed of the  $n - 1$  elements. The value of any given symbol in the string is found by multiplying that symbol by  $n^x$ , where  $x$  is the number of symbols in the string that are to the right of the symbol in question.

For example; in base 10 the number 982 is equal to  $9 * 10^2 + 8 * 10^1 + 2 * 10^0$ .

In base two the number 10101001 is equal to  $1 * 2^7 + 0 * 2^6 + 1 * 2^5 + 0 * 2^4 + 1 * 2^3 + 0 * 2^2 + 0 * 2^1 + 1 * 2^0 = 169$  in base 10.

### A.2 Complex Numbers

A complex number is a number of the form  $a + i * b$ , where  $a$  and  $b$  are real numbers, and  $i$  is defined to be the square root of negative one. Addition of two complex numbers  $c_1$  and  $c_2$  is defined to be:

$$c_1 = a_1 + i * b_1$$

$$c_2 = a_2 + i * b_2$$

$$c_1 + c_2 = a_1 + a_2 + i * (b_1 + b_2)$$

The complex conjugate of a complex number  $c$ , denoted  $c^*$  is defined to be:

$$c = a + i * b$$

$$c^* = a - i * b$$

Multiplication of two complex numbers  $c_1$  and  $c_2$  is defined to be:

$$c_1 = a_1 + i * b_1$$

$$c_2 = a_2 + i * b_2$$

$$c_1 * c_2 = a_1 * a_2 - b_1 * b_2 + i * (a_1 * b_2 + a_2 * b_1)$$

Euler's Formula for complex numbers states that  $e^{ix} = \cos x + i * \sin x$ , this relationship is used in the discrete Fourier transform of Shor's algorithm.

### A.3 Vector Mathematics

The only vector operations that are used in our simulation of Shor's algorithm are addition, length determination, and scaling. The vector in question represents the state vector of a quantum mechanical system; a complex vector in a Hilbert Space. The vector can be represented by projections of the vector onto each of the perpendicular base vectors which define the Hilbert Space.

For example, an  $n$  state quantum system requires a  $n$  dimensional Hilbert Space to represent its state vector. The quantum system can be measured in any of the  $n$  states, and to represent this we imagine each of the  $n$  states as mutually perpendicular axes within our Hilbert space. Thus the state vector for a system in the  $j$ 'th state is equal to:

$$\begin{pmatrix} 0 \\ 0 \\ \vdots \\ 1 \\ \vdots \\ 0 \end{pmatrix}$$

For the  $n$  states, where the number at the top of the column is the length of the state vector projected onto the 1st state, and the 1 appears in the  $j$ 'th row. To add two vectors we simply add their components.

$$\begin{pmatrix} a_1 \\ a_2 \\ a_3 \end{pmatrix} + \begin{pmatrix} b_1 \\ b_2 \\ b_3 \end{pmatrix} = \begin{pmatrix} a_1 + b_1 \\ a_2 + b_2 \\ a_3 + b_3 \end{pmatrix}$$

Since this vector lies in a Hilbert Space the projections of the state vector onto the coordinate axes are allowed to be complex numbers, thus the definition of length is slightly different from what is expected.

The length of a vector in a Hilbert space with  $n$  components is defined to be:  $\sqrt{\sum_{j=1}^n |w_j|^2}$  where  $w_j$  is the value of the  $j$ 'th component of the vector, and  $|w_j|^2$  is defined to be  $w_j$  times its complex conjugate, or when  $w_j = a + i * b$ ,  $|w_j|^2 = a^2 + b^2$ .

To scale a vector by any length  $l$  you simply multiply each component of the vector by the value  $l$ . In particular to scale a vector to length 1 you multiply each component by the inverse length of the vector.

## **B Code for the Simulation of Shor's Algorithm**

## B.1 complex.h

```
#ifndef COMPLEX_H
#define COMPLEX_H

class Complex {
public:
    Complex();           //Default constructor
    ~Complex();         //Default destructor.
    void Set(double new_real, double new_imaginary); //Set data members.
    double Real();      //Return the real part.
    double Imaginary(); //Return the imaginary part.
    Complex operator=(Complex); //Overloaded = operator
    int operator==(Complex);    //Overloaded == operator

}

//Returns the real part of the complex number.
double Complex::Real() {
    return real;
}

//Returns the imaginary part of the complex number.
double Complex::Imaginary() {
    return imaginary;
}
```

### B.3 qureg.C

```
#include <iostream.h>
#include <math.h>
#include <time.h>
#include <stdlib.h>
#include "complex.h"

class QuReg {
public:
    //Default constructor. Size is the size in bits of our register.
    //In our implementation of Shor's algorithm we will need size bits
    //to represent our value for "q" which is a number we have chosen
    //with small prime factors which is between  $2n^2$  and  $3n^2$  inclusive
    //where n is the number we are trying to factor. We envision our the
    //description of our register of size "S" as  $2^S$  complex number,
    //representing the probability of finding the register on one of or
    // $2^S$  base states. Thus we use an array of size  $2^S$ , of Complex
    //numbers. Thus if the size of our register is 3 bits array[7] is
    //the probability amplitude of the state  $|1,1,1\rangle$ , and array[7] *
    //Complex Conjugate(array[7]) = probability of choosing that state.
    //We use normalised state vectors thought the simulation, thus the
    //sum of all possible states times their complex conjugates is = 1.
    QuReg(int size);

    ~QuReg(); //Default destructor.

    int DecMeasure(); //Measures our quantum register, and returns the
    //decimal interpretation of the bitstring measured.

    //Dumps all the information about the quantum register. This has no
    //physical reality, it is only there for debugging. When verbose !=
    //0 we return every value, when verbose = 0 we return only
    //probability amplitudes which differ from 0.
    void Dump(int verbose);

    //Sets state of the qubits using the arrays of complex amplitudes.
    void SetState(Complex new_state[]);

    //Sets the state to an equal superposition of all possible states
    //between 0 and number inclusive.
    void SetAverage(int number);

    //Normalise the state amplitudes.
    void Norm();
};
```

```

//Get the probability of a given state. This is used in the
//discrete Fourier transformation. In a real quantum computer such
//an operation would not be possible, on the flip side, it would
//also not be necessary as you could simply build a DFT gate, and
//run your superposition through it to get the right answer.
Complex GetProb(int state);

//Return the size of the register.
